Abstract

Aims/Background Breast leukaemia (BL) is a rare breast malignancy that is treated differently from other malignant conditions. However, it is easily confused with other conditions; therefore, how to accurately diagnose is crucial. We retrospectively analysed the imaging findings of 13 patients to provide a diagnostic reference.

Methods From January 2015 to April 2023, 13 patients with BL confirmed by biopsy who underwent imaging in Peking University People's hospital were retrospectively analysed. The imaging findings obtained via ultrasound (US), mammography (MMG), magnetic resonance imaging (MRI), and positron emission tomography/computed tomography (PET/CT) were analysed, and the detection rates of these methods for diagnosing BL were compared.

Results Twenty-nine lesions were detected in the 13 patients. These patients presented with palpable masses or breast swelling several months after treatment for leukaemia, mainly involving the bilateral breasts. Ultrasonography was performed for 13 patients, and all lesions were detected. Most of the identified masses were hypoechoic and had indistinct boundaries, irregular shapes, no enhancement of the posterior echo, and no abundant blood flow. MMG was performed for five patients, revealing breast masses, architectural distortion, and no abnormalities. MRI was performed for four patients, and all lesions were detected; most of the lesions were hypointense on T1-weighted imaging and hyperintense on T2-weighted imaging and diffusion-weighted imaging, with a decreased apparent diffusion coefficient and inhomogeneous enhancement. The enhancement curves were mostly inflow patterns. PET/CT was performed for four patients; two patients had hypermetabolism, and the other two had no obvious radioactive uptake.

Conclusion Compared to MMG and PET/CT, US and MRI have higher detection rates. Furthermore, compared to MRI, US is inexpensive, convenient and efficient; therefore, it should be the first choice for diagnosing BL.

Key words: Breast leukaemia; Case report; Imaging findings

Submitted: 18 March 2024; **Revised:** 19 April 2024; **Accepted:** 30 April 2024

Introduction

Breast leukaemia (BL) is a rare breast malignancy that accounts for approximately 0.25% of all breast tumours (Khoury et al, 2000); however, the current description of BL can be found only in case reports. BL is mainly observed in patients with acute myeloid leukaemia and can occur at any age, ranging from 1 to 80 years (Glazebrook et al, 2014; Sung et al, 2023). It often presents as a palpable mass in the breast or breast swelling. BL is caused mainly by extramedullary recurrence of leukaemia, but its specific pathogenesis remains unclear. It may be related to residual microinfiltrating leukaemia lesions, which seed and propagate in the breast, leading to recurrence (Karbasiyan-Esfahani et al, 2008; Chen et al, 2010; Hussain et al, 2022); it may also be related to the abnormal expression of adhesion molecules, the immune phenotype on the cell surface, leukaemia subtypes, or the transformation of tumour cells in the breast microenvironment (Karbasiyan-Esfahani et al, 2008; Liu et al, 2016; Mosalem et al, 2020). BL is easily confused with other breast malignancies that are treated with endocrine therapy or mastectomy (Waks and Winer, 2019). However, unlike for other conditions, there is currently no clear expert consensus on the treatment of BL. Previous studies have used chemotherapy, local radiotherapy, secondary

transplantation, or a treatment combined with novel targeted therapy (Karbasian-Esfahani et al, 2008; Houghtelin et al, 2015; Liu et al, 2016; DiNardo et al, 2023; Shatilova et al, 2021; De Cap et al, 2023; Cunningham, 2006). For BL, if only the discovered lesions or the whole affected breast are resected, other microinvasive lesions within the breast may be missed, leading to postoperative recurrence and ultimately requiring a second operation. Moreover, surgical removal of the breast has permanent physical and psychological effects on patients, significantly reducing their quality of life. Therefore, the accurate identification and diagnosis of BL are highly important. Although the final diagnosis requires histopathology, familiarity with the imaging characteristics of BL can help to establish an accurate diagnosis (Sosa et al, 2022). In this study, the imaging findings of 13 patients with BL were retrospectively analysed to provide a reference for the diagnosis of this disease.

Methods

Patient population

We enrolled 13 patients diagnosed with BL by pathological biopsy who underwent imaging at Peking University People's Hospital from January 2015 to April 2023. Patients who underwent imaging examinations in other hospitals were excluded since we were unable to obtain the images. In total, 29 lesions were identified. Among the included patients, 13 patients underwent ultrasound (US), five patients underwent mammography (MMG), four patients underwent magnetic resonance imaging (MRI), and four patients underwent positron emission tomography/computed tomography (PET/CT). The study was approved by the Ethics Committee of Peking University People's hospital (No. 2018PHB179-01) and was performed in compliance with the Declaration of Helsinki. Written informed consent was obtained from all patients.

Imaging

Mammography

Mammography was performed using a Digital MMG machine (GE Healthcare, Milwaukee, Wisconsin). Standard craniocaudal and mediolateral oblique views were obtained, with additional views if necessary. We reviewed the following features: (1) Breast Imaging Reporting and Data System (BI-RADS) (Spak et al, 2017) classification of the breast parenchyma; (2) density, shape, and boundary of the breast mass; and (3) other associated symptoms (oedema and thickening of the breast skin, inverted nipples, and swelling of the axillary lymph nodes).

Ultrasound

The US instruments used in the study comprised Siemens S3000 (Siemens, Munich, Germany), Logic E9 system (GE Healthcare, Chicago, IL, USA), IU 22 scanner (Philips, Amsterdam, Netherlands), and Mindray DC-8 (Mindray, Shenzhen, China), with high-frequency transducers. We reviewed the following features: (1) lesion position (left, right, or bilateral breast), number (single or multiple), size, composition (cystic or solid), shape (regular or irregular), margin (distinct or indistinct), internal echo (hyperecho, hypoecho, equal echo, or mixed echo), and posterior acoustic enhancement (presence or absence); (2) blood flow (Grade 0, no blood flow; Grade I, a small amount of dot-like blood flow; Grade II, one longer blood flow through the mass or three dot-like blood flows) (Nasief et al, 2019); (3) BI-RADS grade of the lesions determined according to the American College of Radiology (ACR) classification system (Spak et al, 2017); and (4) axillary lymph node involvement (with or without).

Magnetic resonance imaging

We used a 3.0T MRI system scanner (Discovery 750W, GE Healthcare, Chicago, IL, USA) equipped with an 8-channel breast-dedicated coil. The patients were placed in a prone position with natural sagging of both breasts, and scanning of the bilateral breast and

axillary regions was performed. MRI was performed in both the axial and sagittal planes. The breast MRI sequences and scanning order were as follows: (1) axial T2-weighted (T2W) fat-suppressed imaging with a short time inversion recovery (STIR) sequence with the following parameters: repetition time (TR), 3848 ms; echo time (TE), 83 ms; slice thickness, 6.0 mm; slice gap, 1.5 mm; field of view (FOV), 350 mm×350 mm; and matrix, 320×256; (2) diffusion-weighted imaging (DWI) with an echo planar imaging sequence with the following parameters: TR, 3120 ms; TE, 76 ms; slice thickness, 4.0 mm; slice gap, 1.0 mm; FOV, 350 mm×350 mm; matrix, 128×128; and diffusion-sensitive coefficient (b-value), 800 s/mm²; and (3) dynamic contrast-enhanced imaging with a gradient echo sequence, consisting of an axial T1-weighted fat-suppressed sequence with the following parameters: TR, 4.5 ms; TE, 2.1 ms; slice thickness, 1.5 mm; no gap; FOV, 350 mm×350 mm; and matrix, 384×320. After the axial scan, 15 mL of gadopentetate dimeglumine (Magnevist, Bayer HealthCare Pharmaceuticals, Leverkusen, Germany) was injected, at a dose of 0.1 mmol/kg, at a flow rate of 3 mL/s, followed by 20 mL of saline. Twenty-three seconds after the injection, a continuous scan was performed six times, with each scan lasting approximately 60 s, for a total scan time of 6 min 23 s. We reviewed the following characteristics: (1) the presence or absence of a lesion in the breast; (2) lesion shape (circular, lobulated, or irregular), boundary (distinct or indistinct), T1-weighted imaging (T1WI) signal (hyperintensity, hypointensity, or isointensity), T2-weighted imaging (T2WI) signal (hyperintensity, hypointensity, or isointensity), and DWI signal (hyperintensity, hypointensity, or isointensity); (3) lesion enhancement and type of enhancement curve (inflow, outflow, or plateau pattern); (4) BI-RADS grade (Spak et al, 2017).

Positron emission tomography/computed tomography

Positron emission tomography/computed tomography was performed using a GE Discovery PET/CT VCT. All patients fasted for at least 6 h before examination, and their blood glucose level was confirmed to be less than 8 mmol/L. ¹⁸F-Fluorodeoxyglucose (¹⁸F-FDG) was injected intravenously at a dose of 5.55 MBq/kg. Approximately 50 min later, images were acquired from the base of the skull to the sole. PET images were reconstructed using ordered subset expectation maximisation, and the reconstruction parameters were 28 subsets and two iterations. Three-dimensional PET, CT, and their fusion images were reconstructed using computer processing. FDG uptake was considered abnormal when the uptake in the tumour area was significantly greater than that in the background. After correcting for radioactive decay, the maximum standardised uptake value (SUV_{max}) of FDG was semi-quantitatively analysed using the formula $SUV = ROI/ID/BW$, where SUV is the SUV_{max}, ROI is the average region of interest activity (in millicuries per milliliter), ID is the injection dose (in millicuries), and BW is the body weight (in grams). We reviewed (1) the presence or absence of lesions with a high metabolism and (2) the SUV of the lesions.

Results

Patients and clinical signs

A total of 13 patients were enrolled, including 12 (92.31%) females and 1 (7.69%) male. The patients' ages ranged from 17 to 63 years, with an average age of 35 (34.92±13.79) years. Among them, 11 patients (84.62%) presented with palpable masses in the breast, and the sizes of these masses ranged from 0.8 cm to 9.2 cm, with an average of 3.64 (3.64±2.05) cm. The other two patients (15.38%) presented with bilateral breast swelling. All 13 patients developed symptoms after leukaemia treatment; 10 patients (76.92%) developed symptoms 3–22 months after haematopoietic stem cell transplantation (HSCT), with an average of 13 months, and three patients (23.08%) developed symptoms 1–44 months after leukaemia chemotherapy, with an average of 19 months. Among the 13 patients, 8 (61.54%) experienced isolated breast recurrence, whereas the other 5 (38.46%) experienced recurrence not only in the breast (Figure 1A) but also in other parts of the body (Table 1), including the chest wall (Figures 1B, C), retroperitoneum (Figures 1D–F), orbit (Figures 2A–D), eyelid, and skin. In addition, seven patients (53.85%) simultaneously developed graft-vs-host disease (GVHD), involving the intestines, skin, and liver. Four patients (30.77%) had axillary lymph

Figure 1. A 27-year-old woman presented with multiple extramedullary recurrences after haematopoietic stem cell transplantation (HSCT). (A) After 18 months of HSCT, the patient's left breast presented with a mass. (B,C) The patient's whole left breast was resected; 4 months later, the patient's left chest wall exhibited a mass again with abundant blood flow. (D) Twenty-two months later, a retroperitoneal mass appeared (as indicated by the arrows). It was located behind the head of the pancreas and compressed the common bile duct, resulting in obstruction. (E,F) Contrast-enhanced ultrasound (US) showed prominent enhancement in the arterial phase, and the agent quickly washed out (as indicated by the arrows).

Figure 2. A 41-year-old woman presented with a soft tissue mass in the bilateral orbits and breasts 20 months after HSCT. All right extraocular muscles, left superior and inferior rectus muscles, and right optic nerve were involved. The lesions exhibited hyperintensity on T2 STIR images in the sagittal (A,B) and axial (C) views and homogeneous enhancement on T1WI (D). The bilateral breast masses also exhibited hyperintensity on T2 STIR (E) and DWI (F) images and homogeneous enhancement on T1WI (G). STIR, short time inversion recovery; T1WI, T1-weighted imaging; DWI, diffusion-weighted imaging.

Figure 3. Ultrasound images of a 27-year-old woman 18 months after HSCT. The pathological diagnosis was B-lymphoblastic lymphoma/leukaemia. (A–C) There was a hypoechoic mass in the lateral upper quadrant of the left breast, with a well-defined boundary, regular shape, lack of enhancement of posterior echo and abundant blood flow; the elasticity score was 4 points. (D–F) Another hypoechoic mass in the margin of the left breast, with a well-defined boundary, regular shape, and oedema of the peripheral tissue; the elastic score was also 4 points. (G,H) The soft tissue of the axillary region presented with oedema and thickening as well as abundant blood flow.

node enlargement and one patient had edema of axillary soft tissue (Figures 3G,H). The pathologic types included myeloid sarcoma (53.85%), B-cell lymphoblastic lymphoma/leukaemia (30.77%), and T-cell lymphoblastic lymphoma/leukaemia (15.38%) (Table 1).

Ultrasound

Thirteen patients underwent US examination; nine (69.23%) presented with bilateral breast lesions, whereas the other four patients (30.77%) presented with unilateral breast lesions. Eleven patients (84.62%) presented with breast masses, for a total of 29 masses; the other 2 (15.38%) presented with a distorted structure (Figure 4A). The mass characteristics are listed in Table 2. Most of the masses had irregular shapes (68.97%); indistinct boundaries (55.17%); hypoechoic lesions (96.55%) (Figures 3A,D); no enhancement of the posterior echo (79.31%); and no abundant blood flow (58.62%), which was visualised as point or short strip blood flow (grade 0–2), while a few masses had abundant blood flow (Figures 3B,E). Three patients underwent elastography, and their scores were 3, 3 and 4, respectively (Figures 3C,F).

BI-RADS, Breast Imaging Reporting and Data System.

Figure 4. A 20-year-old woman presented with bilateral masses in the breast 12 months after chemotherapy. A core needle biopsy confirmed B-lymphoblastic lymphoma/leukaemia. (A) Distortion of the parenchymal structure of both breasts. (B,C) MMG showed no abnormalities in either breast.

Mammography

Five patients underwent MMG, and their breast parenchymal density was graded as BI-RADS 3 (60.00%) or BI-RADS 4 (40.00%). Among the patients whose breast parenchymal density was graded BI-RADS 3, two patients presented with visible masses (seven masses in total), and the other patient presented only locally heterogeneous density, not a mass. The characteristics of seven masses are presented in [Table 3](#). The other 2 patients with a breast parenchymal density graded as BI-RADS 4 had no abnormalities on MMG ([Figures 4B,C](#)).

Magnetic resonance imaging

Four patients underwent MRI, and 14 lesions were detected. Consistent with the findings of previous studies (Shin, 2016), most of the lesions were slightly hypointense (92.86%) on T1WI and slightly hyperintense (85.71%) on T2WI ([Figures 2E](#) and [5A–C](#)). DWI showed obvious hyperintensity ([Figures 2F](#) and [5D](#)), and the apparent diffusion coefficient (ADC) decreased. The lesions all exhibited significant enhancement, and the enhancement curves were mostly inflow patterns (42.86%) ([Figures 2G](#) and [5E,F](#)) ([Table 4](#)).

Positron emission tomography/computed tomography

Positron emission tomography/computed tomography was performed for four patients, and nine lesions were detected. Six lesions (66.67%) showed intense hypermetabolism ([Figures 6C–E](#)), which were all detected on Ultrasound ([Figures 6A,B](#)). The SUV_{max} ranged from 4.3 to 4.9, with an average of 4.4. The other three (33.33%) lesions did not show obvious uptake of the agent.

Figure 5. Magnetic resonance imaging image of a 17-year-old woman with bilateral breast swelling after 44 months of chemotherapy. Pathology revealed B-lymphoblastic lymphoma/leukaemia. (A–C) The lesions showed hyperintensity in T2WI-STIR images, and the mass in the right breast almost completely replaced the entire breast tissue. (D) The lesions showed hyperintensity on DWI. (E) Contrast-enhanced T1WI showing heterogeneous enhancement. (F) Kinetic analysis obtained from foci within the mass demonstrated rapid enhancement.

Figure 6. Ultrasound and positron emission tomography/computed tomography (PET/CT) images of a 17-year-old woman with bilateral breast swelling after 44 months of chemotherapy. Pathologic analysis revealed B-lymphoblastic lymphoma/leukaemia. US revealed a hypoechoic mass (as indicated by the arrows) in the right (A) and left (B) breasts, and (C,D) PET/CT showed intense hypermetabolism. (E) The maximal intensity projection of PET/CT showed elevated metabolism in both breasts.

Comparison among ultrasound, mammography, magnetic resonance imaging and positron emission tomography/computed tomography

In patients who underwent US and MRI, all the lesions were detected, for a detection rate of 100%, and no false negatives were observed. Among the 5 patients who underwent MMG, two (40.00%) had no significant abnormalities, with a breast parenchymal density grade of BI-RADS 4; however, their US examination all revealed abnormalities, suggesting that the MMG results included false negatives. Similarly, among the four patients who

© 2024 The Author(s).

underwent PET/CT, two (50%) patients did not have hypermetabolic lesions, whereas on US or MRI, all the lesions were detected, suggesting that PET/CT also exhibited false-negative results (Table 5).

Follow-up

We obtained US images of four patients after treatment (Table 5); in two of them, the lesions were significantly reduced. Unfortunately, over time (5 months and 10 months), two patients relapsed again (Figures 7A–F).

Discussion

Breast leukaemia can occur at any age ranging from 1 to 80 years, with a median age of 33 years (Kumar et al, 2010; Glazebrook et al, 2014). In our study, the ages ranged from 17 to 63 years, with an average age of 35 (34.92±13.79) years. BL usually occurs after treatment for leukaemia, and this was the case for all of the patients in our study (Surov et al, 2012; Surov, 2013). The most common pathological type of tumour was myeloid sarcoma (MS), which is consistent with the findings of previous studies (Surov et al, 2012; Ge et al, 2014; Glazebrook et al, 2014). BL usually occurs in bilateral breast, which is different from breast cancer (Yang et al, 2007; Waks and Winer, 2019). This difference may be related to the residual microinvasive lesions in the breasts during leukaemia. According to previous case reports, almost all patients were female, and only one male patient was reported (Chim et al, 2000). In our study, we also included a male who presented with a palpable breast mass 15 months after HSCT but was misdiagnosed with gynaecomastia; this was later confirmed as BL by biopsy. After chemotherapy, the lesions disappeared; however, 5 months later, the lesions relapsed. The possible reason for the relapse may be residual microinvasion of the breasts.

In addition, seven patients developed GVHD; theoretically, GVHD has an antileukemia effect and can prevent the relapse of leukaemia to some extent (Goker et al, 2001; Lee et al, 2005; Karbasian-Esfahani et al, 2008). However, although the seven patients had

Figure 7. Changes in US images of a 24-year-old male after HSCT. (A,B) US image showed a hypoechoic mass on the deep side of both nipples, indicating male gynecomastia. Biopsy confirmed T-lymphoblastic lymphoma/leukaemia. (C, D) After 3 months of chemotherapy, US showed that the lesions had obviously diminished. (E,F) However, 5 months later, the lesions relapsed.

GVHD, they still experienced leukaemia infiltration in the breast and multiple other extramedullary organs. A possible explanation is that GVHD is less effective at preventing extramedullary recurrence because of immune escape or the transformation effect of the breast microenvironment in leukaemia (Gaudichon et al, 2019; Cunningham, 2021); thus, microinvasive lesions in the breast or other organs may not be completely eliminated by GVHD, leading to recurrence after treatment (Galimberti et al, 2006; Pagliuca et al, 2023).

In our study, the most common US characteristic of BL was a mass, which was observed in 11 patients (85.00%). The masses were mainly hypoechoic (92.00%), irregularly shaped (77.00%), and had indistinct boundaries (62.00%) and no enhancement of the posterior echo (77.00%), which was consistent with the results of other reports (Surov et al, 2012; Glazebrook et al, 2014; Aslan and Pourbagher, 2017; Myers et al, 2022). It has been reported that blood flow in BL is abundant (Likaki-Karatza et al, 2002; Surov et al, 2012; Kulkarni et al, 2016; Sager et al, 2019; Kim and Kim, 2019); however, in our study, only a few masses (27%) had abundant blood flow (Grade 3), while the majority (57.00%) had poor blood flow (Grade 0–2). This difference may be related to the sensitivity of the equipment to blood flow or incorrect settings, such as setting the colour scale too high to indicate low-velocity blood flow. In addition, in our study, three patients underwent elastography, and their scores were 3, 3, and 4, respectively, indicating that the tumour was not hard, unlike those observed in breast cancer (Carlsen et al, 2015; Li et al, 2023). This difference might be related to the greater number of tumour cells and fewer fibrous components in the lesions (Abdulkadir et al, 2017; Aslan and Pourbagher, 2017; Lee et al, 2022). However, a low elasticity may affect radiologist judgment, leading to underestimation of the BI-RADS grade (Erduran et al, 1999; Zhang et al, 2020; Masood et al, 2021). Therefore, if malignant US features are found in the breasts of leukaemia patients but the elastography results are low, the possibility of BL should be considered.

In our study, there were three MMG patterns among the 5 patients: breast masses (40.00%), architectural distortion (20.00%), and no abnormalities (40.00%). Consistent with the findings of previous studies (Karbasiyan-Esfahani et al, 2008; Surov et al, 2012; Glazebrook et al, 2014), there were false negatives, possibly due to the high density of the background breast parenchyma, which resulted in the mass being obscured by the dense breast parenchyma and a missed diagnosis. The two patients in our study who presented with false negatives were graded as BI-RADS 4. However, our false-negative rate was greater than those of previous studies, possibly due to differences in breast density among different races. The breast parenchyma of most Chinese women is relatively dense and has little fat; while in most Western countries, women's breasts have more fat, so their density is lower, making it easier to detect masses and resulting in a lower false-negative rate. It can be inferred that for patients with dense breasts, combination of MMG with other methods is needed to reduce the number of missed diagnoses.

In our study, most patients with BL exhibited slight hypointensity (93.00%) on T1WI and slight hyperintensity (86.00%) on T2WI; DWI showed significant hyperintensity, and the ADC decreased, which is consistent with the findings of other studies (Koh and Collins, 2007; Surov et al, 2012; Aslan and Pourbagher, 2017; Sager et al, 2019; Durhan and Demirkazık, 2021; Ghosh et al, 2023; Kim, 2013; Basara and Orguc, 2012). The hyperintensity on DWI and reduced ADC indicate a high cellular composition and density within the tumour, which are characteristic of malignant tumours (Koh and Collins, 2007). A few studies have shown that the ADC of BL is lower than that of breast cancer (Durhan and Demirkazık, 2021). The lesions presented significant enhancement, with three types of enhancement patterns, inflow (42.86%), plateau (35.71%), and outflow (21.43%), which is consistent with the findings of other studies (Surov et al, 2012; Sager et al, 2019; Ghosh et al, 2023).

For patients who underwent ^{18}F -FDG PET/CT, most lesions (67.00%) were hypermetabolic, with an average SUV of 4.4, consistent with the results of other studies (Buck et al, 2004; Glazebrook et al, 2014; Myers et al, 2022). However, a few lesions (33.00%) showed no obvious FDG uptake, although all of these lesions presented as masses on US and were confirmed by biopsy. Thus, we can infer that both the PET/CT and MMG results included false negatives. The reason for these false negatives is not yet clear; it may be related to the diagnostic criteria used to distinguish benign and malignant lesions. If the uptake value of BL is lower than the established criterion, false-negative results may occur. In addition, this difference may also be related to the low resolution of the equipment, small lesion volume, pathological subtypes of BL, and levels of Ki-67 (Buck et al, 2004). To reduce the false-negative rate of PET/CT, a comprehensive judgment should be made according to the clinical history, US, MRI, and other examinations when diagnosing patients. As a whole-body imaging technology, PET/CT has great advantages in disease staging and the evaluation of therapeutic effects (Liu et al, 2016).

Our study has several limitations: it was retrospective, the sample size was small, and not every patient underwent all the imaging examinations. In addition, we did not conduct follow-ups for all patients with every imaging examination; therefore, we did not summarise the general imaging changes after treatment. Methods to detect residual microinvasive lesions more effectively after treatment should be studied. These are promising avenues for future study.

Conclusion

This study is the largest series reporting BL to date, and includes more comprehensive imaging data than previous studies. We found that MMG and PET/CT yield false negatives; in comparison, US and MRI had higher detection rates. Therefore, even if no abnormal lesions are detected on MMG and PET/CT, other imaging methods or clinical history should be performed to make a comprehensive diagnosis of patients with suspected BL. We believe that US is the preferred imaging modality for detecting breast abnormalities in patients with BL; it offers a higher detection rate comparable to MRI, and is more convenient and inexpensive. Since BL is easily confused with other conditions, it is recommended that clinical history be taken into account for diagnosis; in other words, if the patient has leukaemia, we should highly suspect that the lesion in her breast is BL.

Learning points

- The imaging findings of breast leukaemia are nonspecific compared to other breast malignancies, thus incorporating medical history is crucial for accurate diagnosis.
- Ultrasound and MRI have a higher detection rate for breast leukaemia compared to mammography and PET/CT.
- Ultrasound is more accurate than mammography and PET/CT, and more cost-effective than MRI for diagnosing breast leukaemia, making it the preferred initial choice.
- Dense breasts can obscure lesions, posing a significant challenge for mammography.

Author details

¹Department of Ultrasound, Peking University People's Hospital, Beijing, China

Abbreviations

BL, breast leukaemia; US, ultrasound; MMG, mammography; MRI, magnetic resonance imaging; PET/CT, positron emission tomography/computed tomography; T1WI, T1-weighted imaging; T2WI, T2-weighted imaging; STIR, short time inversion recovery; DWI, diffusion-weighted imaging; ADC, apparent diffusion coefficient; BI-RADS, Breast Imaging Reporting and Data System; TR, repetition time; TE, echo time; ¹⁸F-FDG, ¹⁸F-fluorodeoxyglucose; SUV, standardised uptake value; ROI, region of interest; ID, injection dose; BW, body weight; GVHD, graft-vs-host disease; MS, myeloid sarcoma; B-LBL, B-lymphoblastic lymphoma/leukaemia; T-LBL, T-lymphoblastic lymphoma/leukaemia.

Availability of data and materials

All data generated or analysed during this study are included in this article.

Author contributions

DDL, YWX and JAZ designed the research study. DDL performed the research. DDL drafted the manuscript. All authors contributed to important editorial changes in the manuscript. All authors read and approved the final manuscript. All authors have participated sufficiently in the work and agreed to be accountable for all aspects of the work.

Ethics approval and consent to participate

The study was approved by the Ethics Committee of Peking University People's hospital (No. 2018PHB179-01) and was performed in compliance with the Declaration of Helsinki. Written informed consent was obtained from all patients.

Acknowledgements

We are grateful to the patients for their collaboration.

Funding

This research received no external funding.

Conflict of interest

The authors declare no conflict of interest.
